

How Does Superhost Accreditation Benefit Airbnb Hosts in Chicago¹

Yongfei Lu²

June 2020

Abstract

In order to obtain a superhost accreditation, an Airbnb host has to meet a series of strict requirements, including a 90% response rate, 80% 5-star reviews, honor confirmed reservations, etc. However, is it worth the effort to get such an accreditation? How does the superhost status benefit the hosts? Choosing Chicago as our target city, where Airbnb hosts have earned tens of millions of dollars over the 5 biggest weekends in 2019, we take advantage of the k-nearest neighbors(KNN) algorithm, decision tree and multilinear regression models to isolate the effects. Our findings confirm that superhosts do have significantly higher income in comparison with normal hosts. Nevertheless, such accreditation does not bring up their rental price. One critical channel through which superhosts earn more lies in their capacity to maintain a relatively higher occupancy rate, which is achieved mainly through better accommodation services. In addition, even though Chicago has a notorious reputation for high crime rates, safety issues neither appear to bother travelers nor reduce host revenues.

Key words: Airbnb superhost, price, revenue, KNN, decision tree, multilinear.

¹ I'd like to express my gratitude to Professor Richard Evans, who generously provides academic instructions and comments on my work in the past few months. I would also like to thank my classmates of MACS 3250, who unreservedly give me feedback and suggestions on improving my research.

1 Introduction

First proposed by Michael Spence in 1973, signaling theory has made a fundamental impact on our understanding of transactions in the market. According to him, educational credentials serve as reliable signals to employers when they are making hiring decisions in the labor market (Michael, 1973). Scholars further explore the mechanisms under the hood and find that adverse selection in the eBay online market caused by information asymmetries can be mitigated by rich information exchange through bandwidth and technology (Gregory, 2011). Recently, a new form of economy unrolls swiftly in online markets via the platforms like Airbnb, which is named 'sharing economy'. It has been claimed that one standard deviation increase in Airbnb listings is associated with a rise in asking rents of 0.4% in Boston (Keren and Mark, 2017). This, consequently, leads us to questions like how these establishers and lessors apply the signaling theory to build up their own businesses on the Internet. To emit positive signals to consumers, Airbnb has launched the Superhost program since 2019, which certifies those mostly dedicated to providing outstanding hospitality service as superhosts. The focus of the research, therefore, is to explore whether the superhost accreditation benefits Airbnb hosts in the city of Chicago and how the mechanisms work if it is the case.

2 Literature Review

A myriad of research has been done revolving the important attributes that make a room stand out in the market. Even though consumers tend to evaluate their living experience based on past hotel stays, their evaluation standard varies across different cities and differs from that of conventional hotels. Considering the complexity of the relationship between determinants and room price, non-parametric approaches, such as random forest and decision tree models, are employed to identify the critical factors (Manojit and Subrata, 2019). This inspires the researcher to use the decision tree and KNN models to explore what room features are mostly associated with price setting. Through sentiment analysis, 'location', 'amenities' as well as 'host' are the 3 important

factors that contributes to a good living experience for tenants, while ‘noise’ is mostly likely to cause unpleasant comments (Mingming and Xin, 2019). As situations can vary across cities, the researcher would like to investigate how various room features impact travelers’ living experience in the City of Chicago. In particular, combined with Chicago’s crime data, the researcher is keen to check how safety issues concern short-term tenants.

In literature, there are contradictory opinions and assessments on the brand effect. Using the 13-month panel dataset on 1998-99 Internet shopping behavior, researchers show that information use for price comparison weakens the pull of brand by reducing shopping at concentrated branded retailers by approximately one tenth (Waldfoegel and Chen, 2006). In the case of Airbnb, where price comparison is allowed and within easy reach, we can reasonably regard superhost accreditation as the special ‘brand’, or positive signal and explore its effects. In the hedonic price regression model, reputational aspects of the rooms, including rating scores and duration of membership, are found to be associated with economic reward (Timm et al., 2017). However, report from AirDNA shows that on the whole, superhosts charge less on a nightly basis but maintain higher occupancy rate (Scott, 2018). Another research, based on 33 cities listed on Airbnb.com, is contradictory to this and demonstrates that hosts with superhost status, more listings and verified identities usually set prices at a higher level since these are regarded as a kind of quality signals (Dan et al., 2017). As stated before, cases vary across locations. Such difference in research results may stem from use of distinct datasets for different cities. In this case, to develop a clear picture of Chicago, we will use the detailed listing dataset of Chicago.

In conclusion, the literature stated above gives an inspiration for the researcher to explore the specific situation in the city of Chicago. We will firstly apply the KNN model to check whether superhosts charge more. We’ll then explore whether the superhost status exerts a significant influence on revenue and investigate other critical revenue-influencing factors through the decision tree model. On top of this, we’ll further explore the underlying channels by studying what attributes separate superhosts from common ones. The machine learning methods subtly circumvent the limitation of

using linear regression models and thus can more precisely capture the relationship between superhost status and revenue in the City of Chicago. Finally, as the robustness check, we'll use the multilinear regression to check whether the relationship explored above still holds.

3 Data

Figure 3.1 gives the correlation heat map for the main variables of our dataset.

Our main source of data comes directly from insideairbnb.com, an independent, non-commercial and widely used website which provides monthly scraped data from Airbnb. We select the Chicago listing data of August, 2019 to do our research, when huge amounts of income was generated due to high concentration of various festivals. We also merge the dataset with the crime rate data released by Chicago Police Department. After cleaning the raw data, we obtain 8646 observations in our dataset.

Moreover, we create a new variable occupancy rate based on the initially-existent variable reviews per month. The variable is calculated based on following equation, which is supported by the research on the effects of short-term rentals on San Francisco housing market, conducted by Budget and Legislative Analyst's Office in 2015. Here, we take 0.5 for review rate, and 3 for average length of stay. The two estimated values are provided on the insideairbnb website.

$$\text{occupancy rate} = \frac{\text{reviews per month}}{\text{review rate}} \times \frac{\text{average length of stay}}{30}$$

In our research, we mainly focus on variables, including revenue, price, host_is_superhost, avg_yearly_crimes and others indicating accommodation service quality. From the graph, it's obvious that there is a positive correlation between revenue and occupancy rate, while price doesn't seem to be correlated with the superhost status. Price appears to be influenced by cleaning fees and other variables demonstrating how suitable the room is for living, including bedrooms, and other amenities. Besides, even though superhost status doesn't seem to be correlated with rent rate, it is positively correlated various review rating scores and revenue, indicating the potential difference

Figure 3.2 Accommodation Graph

between superhosts and normal ones. On the other hand, Figure 3.2 sheds light on the possible effect of crime rate on host revenues. Somewhat counterintuitively, we haven't

seen any negative effects of average yearly crimes per thousand residents on host revenues. Overall, we've had a big picture of potential relationships among the key variables, then we'll take advantage of different models to isolate our target effects.

4 Methods & Result

4.1 KNN: do Chicago superhosts get a 'brand premium'?

Based on signaling theory, we assume that superhost accreditation sends positive signals to travelers that those with the certificates are mostly dedicated to providing outstanding hospitality services, thereby exerting more market power and raising their prices. To verify the assumption, we choose the KNN model to predict room prices, in which we use Euclidean distance to construct the similarity metric, and take `host_is_superhost` along with other important price-influencing variables as predictors. In the process, we randomly choose 75% of the sample to train the model, which excludes the observations whose price is exorbitantly high (over 1000 dollars per night), and obtain one with a root mean squares error (RMSE) of 89.24. Such a low RMSE value ensures that our model can reliably predict prices for different rooms. Then we counterfactually create two samples by setting the `host_is_superhost` for all the observations of the original dataset to 1 (yes) and 0 respectively and maintaining the original values of the other predictors. We use the trained model to predict the prices for these two samples whose only difference is the value of the `host_is_superhost` variable. Afterwards, we compute the Welch's t-test³ statistics to determine whether the predicted prices for the two samples are significantly different, and it turns out that superhosts don't set a significantly higher price than normal hosts. We get a p-value of 0.97. The result is shown in Figure 4.1.

³ Welch's t-test, or unequal variances t-test, can be used to test the hypothesis that two populations have equal means. It's more reliable when two samples have unequal variances or unequal sample sizes.

KNN prediction price: superhosts vs. normal hosts

Welch's t-test statistics:
T value: -0.034583596067340294
p value: 0.9724121859140163

Figure 4.1 KNN Prediction Result

4.2 Decision Tree: Revenue Prediction

The previous section has shown that superhosts don't set higher prices than normal ones. We now further our exploration to check other channels through which superhosts could gain more benefits. This time we use the non-parametric supervised learning method, decision regression tree, to determine whether superhosts gain more, along with the possible mechanisms. Here, we take revenue as the predicted variable, `host_is_superhost`, `occupancy_rate`, `price` and other variables related to the room equipment as predictors. As shown by Figure 4.2, the decision tree indicates that occupancy rate and price are the two most important predictors. Therefore, if we can demonstrate that superhosts have significant difference from normal hosts in these aspects, then we can conclude that superhost accreditation does influence host revenues. Similarly, we compute the Welch's t-test statistics to identify the differences. Among these predictor variables, we find those (including occupancy rate) which are significantly different among superhosts and normal ones at the 5% significant level, as illustrated by Table 4.2. Therefore, we conclude that superhosts can maintain higher

occupancy rates, thus earning more.

4.3 Linear regression

At last, we use a multilinear regression model to do the robustness check. The models are specified as follows, where S is the superhost status, Z includes all price-influencing variables, and X includes all revenue-influencing factors.

$$Price = \theta + \gamma S + \beta X + u$$

$$Revenue = \alpha + \lambda S + \beta X + \mu$$

(1) Superhosts don't set up higher prices

Table 4.3(1) - price OLS Regressions

From the regression result, we can see that the effect of superhost status on price setting is not significant in Model 1 and 2. While the effect in Model 3 is significant at the 10% significant level, it is negative, which means that superhosts tend to set lower prices (\$4.96 lower than that of normal hosts). The number of bedrooms, bathrooms, and cancellation policy exert significantly positive effects on price. The stricter the cancellation policy, the higher the price.

(2) Superhosts get more revenues by maintaining a higher occupancy rate

From the comparison in section 4.2, we know that superhosts maintain

significantly higher occupancy rates. Now the regression model indicates that one percent increase in occupancy rate leads to an average increase of \$36.64 in host revenues. We therefore conclude that superhosts can benefit from their accreditation by maintaining a relatively higher occupancy rate. Moreover, setting stricter cancellation policies is an effective way to increase income. It's also worth mentioning that renting an entire apartment brings more revenues than renting private or publicly sharing rooms.

(3) Crime rate is not a big concern plaguing the business of Airbnb in Chicago

Even though Chicago has a notorious reputation for high crime rate, our results show that one percent increase in average yearly crimes per thousand residents leads to a \$0.2592 increase in price, and \$1.5551 increase in host revenues. Though significant, the trivial economic effects verify our initial observation of Figure 3.2 that safety issues haven't become a big concern for travelers impairing Airbnb business in Chicago.

5 Conclusion

Based on signaling theory, the research intends to explore the mechanisms through which Airbnb hosts benefit from the superhost accreditation. While research results vary across locations, we focus on the case of the City of Chicago, where Airbnb business flourishes in the context of relatively higher crime rates. We first use KNN prediction model to check whether superhosts set higher prices, and then apply decision tree to extract important revenue-influencing factors. In comparison with traditional parametric approaches, these machine learning methods can more precisely capture our target relationship. Finally, we use multilinear regression, which is also good at explaining the effects, to do a robustness check. Our research confirms that superhosts don't ask a higher price, but instead decrease their price a little bit and maintain a significantly higher occupancy rate, thereby increasing their revenues. In addition, the city's reputation of high crime rates does not impair the Airbnb short-term

rental business.

While the research yields consistent results, it does have limitations that need further disposal. As we calculate the occupancy rate based on certain already-existent variables, we may introduce error to our estimation. Besides, we only focus on the period in a year when huge amounts of revenues are generated, therefore may omit some other important patterns. In the future, we may need to develop a more precise model to estimate the occupancy rate, and use more extensive dataset to conduct our investigation.
